

S.1 EI, HRV, and HR

Neither ability EI nor mixed EI were significant predictors of baseline HRV or HR (Figure 2, Panels C-F). See Table S2 for HRV model coefficients, sums of squares, and partial eta-squared and Table S3 for HR model coefficients, sums of squares, and partial eta-squared.

Physiological Response to Serial Subtraction

A linear mixed model established that participants did not have significant changes in HRV during the stress reactivity assessment, $F(2, 300) = 2.45, p = .09$. An additional linear mixed model indicated that participants did have significant increases in HR in response to the stress induction and no change relative to baseline levels during recovery, $F(2, 300) = 81.59, p < .0001$. See Table S4 for model coefficients, standard errors, and beta values.

EI Predicting Change Across Conditions

No interactions or main effects for EI and HRV across conditions were observed for any EI measures of interest. See Table S6 for HRV model coefficients, standard errors, and beta values. There were also no interactions or main effects for EI and HR across conditions. See Table S7 for HR model coefficients, standard errors, and beta values.

S.2 Investigating the Potential Influence of Covariates

The combination of gender and caffeine was not favored over the simpler model main effect model only including RMSSD and EI, $L.Ratio = 0.46, p = .79$. The addition of gender independently, $L.Ratio = 0.03, p = .86$, or caffeine used, $L.Ratio = 0.42, p = .52$, were also not

favorable over the simpler main effects models when interrogated on their inclusion. The combination of both covariates was also not favored over the simpler model main effect model only including HRV and EI, $L.Ratio = 1.65, p = .44$. The addition of gender independently, $L.Ratio = 0.76, p = .38$, or caffeine used, $L.Ratio = 0.80, p = .37$, were also not favored over the simpler main effects models when interrogated on their inclusion. The combination of both covariates was not favored over the simpler model main effect model only including HR and EI, $L.Ratio = 1.42, p = .49$. The addition of gender independently, $L.Ratio = 1.34, p = .25$, or caffeine used, $L.Ratio = 0.11, p = .74$, were also not favored over the simpler main effects models when interrogated on their inclusion.

S.3 Exploring Individual Differences in CVC in Response to Stress and Recovery

Zero-Order Subscale Correlation Analysis

Bivariate correlations assessing relationships among RMSSD, HRV, and HR at baseline resting levels, change from the prior level during stress induction and during resting recovery, MSCEIT subscale scores, and EQi subscale scores across the total sample. The MSCEIT understanding branch showed positive associations with baseline RMSSD and negative associations with change in RMSSD from baseline to stress induction. The MSCEIT managing branch showed positive associations with change in RMSSD from stress induction to resting recovery. The EQi decision-making branch and self-expression branch showed negative associations with change in RMSSD from baseline to stress induction. The EQi decision-making branch and self-perception branch showed positive associations with change in RMSSD from stress induction to resting recovery. None of the observed associations remained significant after Bonferroni correction for

multiple comparisons. See Figure S.1 for Spearman correlation coefficients with HRV and with HR.

Table S1. EI Scores Predicting RMSSD at Rest Linear Models

Baseline RMSSD During Rest					
<i>Predictors</i>	<i>SS</i>	<i>df</i>	<i>F</i>	<i>p</i>	<i>Partial η^2</i>
